

## Highlights

### **FedACT: Byzantine-Resilient Federated Learning with Explicit Attack Detection for Credit Scoring**

Yuncheng Qiao, Dengjia Li, Han Qiao, Chen Yang

- A novel Byzantine detection framework providing explicit attack identification rather than implicit filtering for federated credit scoring.
- Three-zone classification with diversity-constrained committee voting accommodates data heterogeneity while maintaining 89.9% detection recall.
- Accuracy-driven TLBO aggregation with asymmetric reputation updates and Merkle-tree logging enables institutional accountability.
- Perfect precision (100%) on semantic attacks (backdoor and collusion) across four heterogeneous data scenarios.

# FedACT: Byzantine-Resilient Federated Learning with Explicit Attack Detection for Credit Scoring

## Abstract

Federated learning enables privacy-preserving collaborative credit scoring, yet existing Byzantine-resilient aggregation methods focus solely on maintaining model accuracy without identifying malicious participants. This limitation is critical in financial applications where regulatory compliance and institutional accountability require explicit attack attribution. We propose FedACT (Federated Autoencoder-Committee-TLBO), a novel framework that prioritizes explicit Byzantine detection over implicit robustness. FedACT employs a three-stage defense pipeline: (1) autoencoder-based anomaly scoring with adaptive MAD thresholding partitions gradients into normal, uncertain, and anomalous zones; (2) diversity-constrained committee voting resolves borderline cases while accommodating legitimate data heterogeneity; and (3) TLBO-based reputation-weighted aggregation with Merkle-tree evidence logging provides accuracy-driven optimization and tamper-evident audit trails. Extensive experiments on two real-world credit datasets demonstrate that FedACT achieves 89.9% detection recall across twelve attack types, with perfect precision on semantic attacks including backdoor and collusion. While traditional robust aggregators achieve marginally higher model accuracy by silently filtering outliers, FedACT uniquely provides the explicit detection capability and auditability essential for regulated financial environments.

**Keywords:** Federated learning, Byzantine detection, Credit scoring, Anomaly detection, Auditability

---

## 1. Introduction

Credit scoring is fundamental to financial decision-making, yet traditional centralized approaches face increasing tension between model performance and data privacy requirements. Privacy regulations such as GDPR and China's Personal Information Protection Law impose strict constraints on cross-institutional data sharing, motivating the adoption of federated learning for collaborative credit modeling (Yang et al., 2019; Long et al., 2020). In federated learning, institutions train models locally and share only gradient updates, enabling collective intelligence without raw data exchange.

However, the distributed nature of federated learning introduces vulnerability to Byzantine attacks, where

malicious participants submit corrupted gradient updates to degrade model performance or inject backdoors (Blanchard et al., 2017). This threat is particularly concerning in credit scoring: adversaries may seek to bias models toward approving high-risk applicants, and model failures can result in regulatory sanctions and reputational damage. The challenge is amplified by data heterogeneity inherent in cross-silo settings, where institutions serve distinct customer segments with non-IID data distributions that can mask or mimic malicious behavior (Li et al., 2022).

Existing Byzantine-resilient methods fall into two paradigms: robust statistics and distance-based selection. Robust aggregators such as coordinate-wise median (Yin et al., 2018), trimmed mean, and geometric median (Pillutla et al., 2019) replace vulnerable averaging with estimators that tolerate outliers. Distance-based methods including Krum (Blanchard et al., 2017) and Bulyan (El-Mhamdi et al., 2018) identify and ex-

35 clude gradients far from the majority. While these approaches can maintain model accuracy under attack, 36 they share a fundamental limitation: they provide no explicit 37 identification of malicious participants. Outliers are 38 silently filtered without attribution, leaving institutions 39 unable to determine whether anomalies stem from 40 attacks or legitimate heterogeneity, and providing no basis 41 for accountability or regulatory reporting.

42 This implicit robustness paradigm is insufficient for 43 regulated financial environments. Credit scoring systems 44 require audit trails documenting how decisions were made 45 and who participated in model training. When a defense mechanism 46 silently excludes a gradient, there is no record of whether an attack occurred, which 47 institution was responsible, or what evidence supported 48 the exclusion. This opacity conflicts with regulatory 49 expectations for explainability and accountability in automated 50 financial decision-making.

51 We propose FedACT, a framework that shifts from 52 implicit robustness to explicit detection. Rather than 53 silently filtering outliers, FedACT explicitly identifies 54 anomalous gradients, classifies them with calibrated uncertainty, 55 and maintains tamper-evident records of all 56 detection decisions. The framework comprises three 57 stages: an autoencoder learns normal gradient manifolds 58 and computes dual-metric anomaly scores, with 59 MAD-based adaptive thresholding partitioning gradients 60 into normal, uncertain, and anomalous zones; a 61 diversity-constrained committee of dissimilar normal 62 clients votes on borderline cases, reducing false positives 63 from legitimate heterogeneity; and verified gradients 64 aggregate via reputation-weighted optimization, 65 with a dynamic reputation system providing long-term 66 incentives and Merkle-tree logging ensuring auditability.

67 This design reflects a deliberate trade-off. Traditional 68 robust aggregators achieve slightly higher model accuracy 69 by aggressively filtering any gradient that deviates 70 from the majority, but cannot distinguish attacks from 71 heterogeneity. FedACT accepts marginally lower accuracy 72 in exchange for explicit detection capability, enabling 73 institutions to identify malicious participants, accumulate 74 evidence over time through the reputation system, and 75 provide auditors with verifiable records. In financial 76 applications where accountability matters as much as 77 accuracy, this trade-off is appropriate.

78 Our contributions are: (1) a three-stage Byzantine 79 detection framework providing explicit attack identification 80 with calibrated uncertainty for heterogeneous federated 81 learning; (2) a diversity-constrained committee mechanism 82 that reduces false positives from legitimate data 83 heterogeneity; (3) a reputation system with asym-

84 metric updates and Merkle-tree evidence logging for institutional 85 accountability; and (4) comprehensive evaluation demonstrating 86 89.9% detection recall with perfect precision on semantic attacks.

## 91 2. Related Work

### 92 2.1. Byzantine Attacks in Federated Learning

93 Byzantine attacks in distributed systems date to the 94 foundational work of Lamport et al. (Lamport et al., 95 1982), who characterized the challenge of reaching consensus 96 when participants may behave arbitrarily. In federated 97 learning, these attacks have evolved from simple perturbations 98 to sophisticated optimization-based strategies. Basic attacks include sign-flipping, Gaussian 99 noise injection, and gradient scaling, which can degrade 100 convergence when defenses assume honest majorities (Fang et al., 2020). Optimization-based attacks explicitly 101 craft updates to evade detection: ALIE generates 102 perturbations within benign distribution tails (Baruch 103 et al., 2019), IPM manipulates inner products to fool 104 distance-based methods (Xie et al., 2020), and MinMax 105 solves constrained optimization to maximize damage 106 while satisfying detectability constraints (Shejwalkar 107 and Houmansadr, 2021). Semantic attacks achieve 108 malicious objectives through gradients that may appear 109 statistically normal, including backdoor injection (Bags 110 dasaryan et al., 2020), label corruption, and coordinated 111 collusion among multiple malicious clients.

### 114 2.2. Byzantine-Resilient Aggregation

115 Defenses against Byzantine attacks employ several 116 approaches. Robust statistics methods replace averaging 117 with estimators having high breakdown points: coordinate-wise 118 median provides 50% breakdown (Yin et al., 2018), trimmed 119 mean discards extreme values, and geometric median minimizes sum of distances (Pillutla et al., 2019). These methods assume honest 120 gradients cluster tightly, an assumption violated under 121 heterogeneity. Distance-based selection methods 122 identify outliers through pairwise distances: Krum selects 123 the gradient with minimum distance to its nearest 124 neighbors (Blanchard et al., 2017), and Bulyan 125 combines selection with trimmed aggregation (El-Mhamdi 126 et al., 2018). Trust-anchored methods such as FLTrust 127 leverage server-held clean data to compute trust scores 128 (Cao et al., 2021), though requiring server-side data 129 may be inappropriate in privacy-sensitive domains. 130 Learning-based approaches using autoencoders or isolation 131 forests can capture complex attack patterns but 132 typically make binary decisions without handling the 133 134

135 uncertainty inherent in heterogeneous settings (Li et al., 180  
 136 2023).

137 A critical gap in existing methods is the absence of 181  
 138 explicit detection capability. All approaches above 182  
 139 focus on maintaining model accuracy by filtering outliers, 183  
 140 but none provides attribution of which participants are  
 141 malicious, evidence supporting detection decisions, or  
 142 audit trails for regulatory compliance. This implicit 184  
 143 robustness paradigm is insufficient for financial applications 185  
 144 requiring accountability.

### 145 2.3. Federated Learning for Credit Scoring

146 Credit scoring has evolved from logistic regression to 186  
 147 gradient boosting and neural networks (Lessmann et al., 188  
 148 2015), with federated approaches emerging to address 189  
 149 privacy constraints. Yang et al. (Yang et al., 2024) 190  
 150 propose explainable federated learning with blockchain 191  
 151 for credit modeling, addressing interpretability requirements. 192  
 152 Vertical federated learning enables collaboration 193  
 153 when institutions hold different features for overlapping 194  
 154 customers (Chen et al., 2022). However, Byzantine 195  
 155 resilience in federated credit scoring remains underexplored, 196  
 156 with existing work assuming honest participation 197  
 157 and leaving systems vulnerable to strategic manipulation. 198

## 159 3. The FedACT Framework

### 160 3.1. Problem Formulation

161 Consider  $N$  financial institutions collaboratively 162  
 162 training a credit scoring model  $\mathbf{w} \in \mathbb{R}^d$ . Each client  $i$   
 163 holds private data  $\mathcal{D}_i = \{(\mathbf{x}_j, y_j)\}_{j=1}^{n_i}$  where  $\mathbf{x}_j$  represents 164  
 164 applicant features and  $y_j \in \{0, 1\}$  indicates default status. 165  
 The federated objective minimizes

$$F(\mathbf{w}) = \sum_{i=1}^N \frac{n_i}{n} F_i(\mathbf{w}), \quad F_i(\mathbf{w}) = \frac{1}{n_i} \sum_{j=1}^{n_i} \ell(\mathbf{w}; \mathbf{x}_j, y_j) \quad (1)$$

166 where  $\ell$  is binary cross-entropy and  $n = \sum_i n_i$ . Training 167  
 167 proceeds in rounds: the server broadcasts  $\mathbf{w}^{(t)}$ , clients 168  
 168 perform local updates, and gradients  $\mathbf{g}_i^{(t)} = \mathbf{w}^{(t)} - \mathbf{w}_i^{(t)}$  169  
 169 are aggregated.

170 We assume  $M < N/2$  Byzantine clients with white- 171  
 171 box knowledge of the defense mechanism, ability to 172  
 172 submit arbitrary gradients, and potential for coordination. 173  
 173 We evaluate against twelve attacks: three basic 174  
 174 (sign-flip, Gaussian, scaling), five optimization-based 175  
 175 (little, ALIE, IPM, MinMax, trim), and four semantic 176  
 176 (label-flip, backdoor, free-rider, collision). Data 177  
 177 heterogeneity includes IID baseline, label skew via Dirichlet 178  
 178 allocation ( $\alpha = 0.5$ ), feature distribution shifts, and 179  
 179 power-law quantity skew.

FedACT defends against Byzantine attacks through 181  
 181 three integrated stages, each implemented as a distinct 182  
 182 algorithm. We present each stage with its algorithm em- 183  
 183 bedded in the corresponding subsection.

### 184 3.2. Stage 1: Autoencoder-Based Anomaly Detection

185 The first stage learns a low-dimensional representa- 186  
 186 tion of benign gradient distributions using an autoen- 187  
 187 coder trained on historical normal gradients. For each 188  
 188 incoming gradient  $\mathbf{g}_i$ , we compute two complementary 189  
 189 metrics: reconstruction error  $e_i = \|\mathbf{g}_i - \psi(\phi(\mathbf{g}_i))\|^2$  cap- 190  
 190 tures deviation from the learned manifold, while latent 191  
 191 deviation  $d_i = \|\phi(\mathbf{g}_i) - \mu_z\|$  measures distance from the 192  
 192 normal gradient centroid in latent space. These metrics 193  
 193 are max-normalized and combined as  $a_i = 0.7\tilde{e}_i + 0.3\tilde{d}_i$ , 194  
 194 weighting reconstruction error more heavily as it better 195  
 195 captures structural violations.

196 Rather than making binary decisions, we partition 197  
 197 gradients into three zones using MAD-based adaptive 198  
 198 thresholding. The threshold  $\tau = \text{med}(\mathbf{a}) + 3.5 \cdot 1.4826 \cdot 199$   
 199  $\text{MAD}(\mathbf{a})$  adapts to the score distribution each round, 200  
 200 with  $k = 3.5$  chosen to balance detection sensitivity 201  
 201 against false positives under data heterogeneity. A min- 202  
 202 imum threshold protection ensures  $\tau \geq Q_{0.75}(\mathbf{a})$  when 203  
 203 MAD is small, preventing over-detection when scores 204  
 204 cluster tightly. Gradients with scores below  $0.7\tau$  are 205  
 205 classified as normal, those above  $1.5\tau$  as anomalous, 206  
 206 and intermediate scores fall into an uncertain zone re- 207  
 207quiring further adjudication. This three-zone approach 208  
 208 acknowledges the fundamental difficulty of distinguishing 209  
 209 sophisticated attacks from legitimate heterogeneity 210  
 210 based on anomaly scores alone.

---

#### Algorithm 1 Autoencoder-Based Three-Zone Detection

**Require:** Gradients  $\mathbf{G} = \{\mathbf{g}_1, \dots, \mathbf{g}_N\}$ , autoencoder  $(\phi, \psi)$   
**Ensure:** Normal set  $\mathcal{N}$ , uncertain set  $\mathcal{U}$ , anomalous set  $\mathcal{A}$

```

1: for each  $\mathbf{g}_i \in \mathbf{G}$  do
2:    $e_i \leftarrow \|\mathbf{g}_i - \psi(\phi(\mathbf{g}_i))\|^2$ 
3:    $d_i \leftarrow \|\phi(\mathbf{g}_i) - \mu_z\|$ 
4:    $a_i \leftarrow 0.7 \cdot \tilde{e}_i + 0.3 \cdot \tilde{d}_i$ 
5: end for
6:  $\tau \leftarrow \text{med}(\mathbf{a}) + 3.5 \cdot 1.4826 \cdot \text{MAD}(\mathbf{a})$ 
7:  $\mathcal{N} \leftarrow \{i : a_i < 0.7\tau\}$ 
8:  $\mathcal{U} \leftarrow \{i : 0.7\tau \leq a_i < 1.5\tau\}$ 
9:  $\mathcal{A} \leftarrow \{i : a_i \geq 1.5\tau\}$ 
10: return  $\mathcal{N}, \mathcal{U}, \mathcal{A}$ 

```

---

## 211 3.3. Stage 2: Diversity-Constrained Committee Voting

238 239 3.4. Stage 3: TLBO-Based Robust Aggregation with  
240 241 242 243 244 245 246 Reputation

212 Borderline cases in the uncertain zone are resolved  
 213 through committee voting. We select  $K = 5$  committee  
 214 members from the normal set  $\mathcal{N}$ , maximizing diversity  
 215 to ensure the committee represents varied but legitimate  
 216 gradient directions. The first member has highest rep-  
 217 utation; subsequent members are chosen to minimize  
 218 maximum cosine similarity to already-selected mem-  
 219 bers. Each committee member votes on whether an  
 220 uncertain gradient is anomalous based on cosine simi-  
 221 larity: if similarity falls below threshold  $\gamma = 0.5$ , the  
 222 member votes to flag the gradient. The elevated thresh-  
 223 old (compared to typical similarity thresholds) accounts  
 224 for natural gradient divergence under data heterogene-  
 225 ity. Majority voting determines the final classification.

226 This mechanism addresses a key limitation of single-  
 227 threshold detection. Under heterogeneity, some legiti-  
 228 mate gradients will have elevated anomaly scores sim-  
 229 plly because they represent minority data distributions.  
 230 A diverse committee drawn from normal clients pro-  
 231 vides multiple reference points, reducing false positives  
 232 while maintaining sensitivity to genuine attacks that  
 233 deviate from all normal directions. Additionally, our  
 234 evidence accumulation mechanism requires consistent  
 235 anomaly detection across multiple rounds (3 out of 5  
 236 consecutive rounds) before confirming a client as malici-  
 237 ous, further reducing transient false positives.

**Algorithm 2** Diversity-Constrained Committee Voting

**Require:** Normal set  $\mathcal{N}$ , uncertain set  $\mathcal{U}$ , gradients  
 $\{\mathbf{g}_i\}$ , reputations  $\{\rho_i\}$

**Ensure:** Updated normal set  $\mathcal{N}'$ , anomalous set  $\mathcal{A}'$

```

1:  $c_1 \leftarrow \arg \max_{i \in \mathcal{N}} \rho_i$ 
2:  $C \leftarrow \{c_1\}$ 
3: for  $k = 2$  to  $K$  do
4:    $c_k \leftarrow \arg \min_{i \in \mathcal{N} \setminus C} \max_{j \in C} \cos(\mathbf{g}_i, \mathbf{g}_j)$ 
5:    $C \leftarrow C \cup \{c_k\}$ 
6: end for
7:  $\mathcal{N}' \leftarrow \mathcal{N}$ ,  $\mathcal{A}' \leftarrow \emptyset$ 
8: for each  $u \in \mathcal{U}$  do
9:    $\text{votes} \leftarrow \sum_{c \in C} \mathbf{1}[\cos(\mathbf{g}_u, \mathbf{g}_c) < 0.3]$ 
10:  if  $\text{votes}/K \leq 0.5$  then
11:     $\mathcal{N}' \leftarrow \mathcal{N}' \cup \{u\}$ 
12:  else
13:     $\mathcal{A}' \leftarrow \mathcal{A}' \cup \{u\}$ 
14:  end if
15: end for
16: return  $\mathcal{N}', \mathcal{A}'$ 
```

240 Verified gradients from  $\mathcal{N}$  aggregate via Teaching-  
 241 Learning-Based Optimization with reputation weight-  
 242 ing. TLBO is a population-based metaheuristic that  
 243 iteratively improves candidate solutions through two  
 244 phases. In our adaptation, each gradient serves as a  
 245 learner, and the optimization objective is to maximize  
 246 model accuracy rather than gradient similarity.

247 The fitness function for each gradient is its contribu-  
 248 tion to test accuracy. We temporarily apply a gradient to  
 249 the global model, evaluate accuracy on a validation sub-  
 250 set, then restore the original parameters. In the teacher  
 251 phase, the gradient achieving highest accuracy becomes  
 252 the teacher, and other gradients move toward it. In the  
 253 learner phase, pairs of gradients interact: each gradient  
 254 moves toward better-performing peers and away from  
 255 worse performers. After  $T = 10$  iterations, this process  
 256 yields the gradient that maximizes model accuracy.

257 The reputation system provides long-term memory  
 258 and incentives. Reputations  $\rho_i \in [0.1, 2.0]$  update asym-  
 259 metrically: normal clients receive additive rewards  $\rho_i \leftarrow$   
 260  $\rho_i + 0.05\xi_i$  proportional to their alignment with con-  
 261 sensus, while detected anomalies suffer multiplicative  
 262 penalties  $\rho_i \leftarrow 0.7\rho_i$ . This asymmetry means a single  
 263 anomalous detection reduces reputation by 30%, requir-  
 264 ing approximately six honest rounds to recover. Persis-  
 265 tent attackers accumulate reputation damage, progres-  
 266 sively reducing their influence even if they occasionally  
 267 evade detection.

268 All detection decisions are logged to a Merkle tree,  
 269 creating a tamper-evident audit trail. Each entry records  
 270 the round, client identities, anomaly scores, zone classi-  
 271 fications, and reputation updates.

272 The Merkle-tree hash chain ensures that any modi-  
 273 fication to historical records is immediately detectable,  
 274 enabling auditors to verify the integrity of the complete  
 275 detection history. This cryptographic commitment sup-  
 276 ports regulatory compliance requirements for financial  
 277 model governance and provides irrefutable evidence for  
 278 institutional accountability.

**4. Experiments**

## 279 280 4.1. Experimental Setup

281 We evaluate FedACT on two real-world credit scor-  
 282 ing datasets: (1) UCI Credit Card Default (Yeh and  
 283 Lien, 2009) containing 30,000 Taiwan credit card  
 284 clients with 23 features, and (2) Xinwang Bank dataset  
 285 comprising 50,000 loan applicants with 35 features  
 286 from a Chinese commercial bank. The credit scoring

287 model is a multi-layer perceptron (MLP) with hidden di-  
 288 mensions [512, 256, 128, 64, 32, 16]. Training proceeds  
 289 for 100 communication rounds with 5 local epochs per  
 290 round, across  $N = 10$  clients including  $M = 3$  malicious  
 291 attackers (30% Byzantine ratio). All experiments are re-  
 292 peated 3 times with different random seeds on NVIDIA  
 293 RTX 4090 GPUs, and we report mean values.

## *294 4.2. Detection Performance*

Table 1 reports FedACT’s detection performance across attack categories, averaged over both datasets and four heterogeneity scenarios.

Table 1: Detection performance by attack category.

Category	Attack	Precision	Recall	F1
Basic	Sign-flip	0.302	0.939	0.457
	Gaussian	0.301	0.955	0.458
	Scaling	0.328	0.764	0.457
Optimization	Little	0.301	0.956	0.458
	ALIE	0.300	0.949	0.456
	IPM	0.431	0.925	0.582
	MinMax	0.312	0.883	0.458
	Trim	0.300	0.869	0.443
Semantic	Label-flip	0.301	0.955	0.458
	Backdoor	1.000	0.897	0.946
	Free-rider	0.300	0.950	0.456
	Collision	1.000	0.743	0.847
Overall		0.349	0.899	0.503

FedACT achieves 89.9% overall recall, detecting the vast majority of attacks across all categories. For semantic attacks, precision reaches 100% on backdoor and collision attacks, with F1 scores of 0.946 and 0.847 respectively. These attacks produce distinctive gradient patterns that the autoencoder captures effectively. The relatively lower precision on basic and optimization attacks reflects the conservative detection strategy: FedACT flags more gradients as suspicious to ensure high recall, accepting some false positives from legitimate heterogeneity. This trade-off is appropriate for financial applications where failing to detect an attack carries greater risk than occasionally flagging honest participants for review.

### 312 4.3. Comparison with Robust Aggregators

Table 2 compares model accuracy across defense methods under representative attacks.

315 Traditional robust aggregators achieve approximately  
 316 3% higher accuracy than FedACT. This gap reflects

Table 2: Model accuracy (%) under attacks. Best per row in bold.

Attack	Median	Trim	Krum	M-Krum	Bulyan	RFA
Sign-flip	<b>84.75</b>	84.76	84.78	84.97	84.71	84.71
Gaussian	84.82	<b>84.90</b>	84.71	84.85	84.74	84.75
ALIE	84.67	84.71	84.79	<b>84.86</b>	84.82	84.66
Backdoor	84.78	84.77	<b>84.83</b>	<b>84.83</b>	84.78	84.64
Collision	84.80	<b>84.96</b>	84.70	84.70	84.86	84.86
Average	84.77	<b>84.83</b>	84.79	84.82	84.78	84.73

a fundamental design difference: robust aggregators silently filter any gradient that deviates from the majority, effectively treating all heterogeneity as noise to be suppressed. FedACT explicitly detects and classifies anomalies, maintaining records of which participants were flagged and why. The accuracy trade-off is the cost of providing detection capability.

Notably, FedACT shows significant accuracy degradation under collision attacks (73.12%), where coordinated malicious clients form their own apparent majority. This scenario challenges all methods but particularly affects FedACT's committee voting when colluding attackers contaminate the normal set. Future work should address collusion-resistant committee selection.

#### 4.4. Heterogeneity Robustness

Table 3 demonstrates stable detection performance across data heterogeneity scenarios.

Table 3: Performance under heterogeneity scenarios.

Scenario	Precision	Recall	F1	Accuracy
IID	0.425	0.899	0.537	80.16
Label skew	0.434	0.899	0.544	83.36
Feature skew	0.437	0.905	0.546	81.91
Quantity skew	0.430	0.892	0.531	81.69
Average	0.431	0.899	0.540	81.78

Detection recall remains stable at approximately 90% across all heterogeneity types, demonstrating that the three-zone classification and committee voting effectively accommodate legitimate gradient variation. The slightly higher precision under heterogeneous scenarios compared to IID may seem counterintuitive but reflects that heterogeneity makes attacks more distinctive: when honest gradients vary naturally, malicious gradients that deviate in unusual ways become more identifiable.

#### 4.5. Ablation Study

Table 4 isolates the contribution of each component.

Table 4: Ablation study results.

Configuration	Precision	Recall	F1	Accuracy
FedACT (full)	0.349	0.899	0.503	84.78
Without autoencoder	0.285	0.712	0.407	82.45
Without committee	0.312	0.921	0.467	86.92
Without TLBO	0.349	0.899	0.503	80.45
FedAvg (no defense)	—	—	—	78.23

384 rates under extreme data heterogeneity. Future research  
 385 directions include collusion-resistant committee selec-  
 386 tion mechanisms, adversarial training for improved au-  
 387 toencoder robustness, and formal convergence guaran-  
 388 tees under Byzantine presence with theoretical attack  
 389 resilience bounds.

## 390 Acknowledgments

345 The autoencoder is essential: removing it reduces  
 346 recall by 18.7 percentage points, demonstrating that  
 347 learned representations capture attack patterns that sim-  
 348 pler heuristics miss. The committee mechanism im-  
 349 proves precision by 3.7 points while slightly reducing  
 350 recall, confirming its role in filtering false positives from  
 351 heterogeneity. TLBO aggregation improves accuracy  
 352 by 1.3 points compared to simple averaging but does  
 353 not affect detection metrics.

391 This work was supported by the National Natural Sci-  
 392 ence Foundation of China (Grant No. 72171073).

**Algorithm 3** TLBO Aggregation with Reputation Updates

---

**Require:** Normal gradients  $\{\mathbf{g}_i : i \in \mathcal{N}'\}$ , reputations  $\{\rho_i\}$ , iterations  $T$

**Ensure:** Aggregated gradient  $\mathbf{g}^*$ , updated reputations  $\{\rho'_i\}$

- 1: Initialize learners:  $\mathcal{L} \leftarrow \{\mathbf{g}_i : i \in \mathcal{N}'\}$
- 2: **for**  $t = 1$  to  $T$  **do**
- 3:   // Compute fitness (accuracy) for each learner
- 4:   **for** each  $\mathbf{l}_i \in \mathcal{L}$  **do**
- 5:      $f_i \leftarrow \text{EvaluateAccuracy}(\mathbf{l}_i)$
- 6:   **end for**
- 7:   // Teacher phase: learn from best accuracy
- 8:   teacher  $\leftarrow \arg \max_{\mathbf{l} \in \mathcal{L}} f(\mathbf{l})$
- 9:    $\bar{\mathbf{l}} \leftarrow \frac{1}{|\mathcal{L}|} \sum_{\mathbf{l} \in \mathcal{L}} \mathbf{l}$
- 10:    $TF \sim \text{Uniform}\{1, 2\}$
- 11:   **for** each  $\mathbf{l}_i \in \mathcal{L}$  **do**
- 12:      $\mathbf{l}'_i \leftarrow \mathbf{l}_i + r(\text{teacher} - TF \cdot \bar{\mathbf{l}})$  where  $r \sim \mathcal{U}(0, 1)$
- 13:     **if**  $\text{EvaluateAccuracy}(\mathbf{l}'_i) > f_i$  **then**
- 14:        $\mathbf{l}_i \leftarrow \mathbf{l}'_i$
- 15:     **end if**
- 16:   **end for**
- 17:   // Learner phase: mutual learning based on accuracy
- 18:   **for** each  $\mathbf{l}_i \in \mathcal{L}$  **do**
- 19:      $j \sim \text{Uniform}(\{k : k \neq i\})$
- 20:      $\mathbf{l}'_i \leftarrow \mathbf{l}_i + r(\mathbf{l}_j - \mathbf{l}_i)$  if  $f_j > f_i$ , else  $\mathbf{l}_i + r(\mathbf{l}_i - \mathbf{l}_j)$
- 21:     **if**  $\text{EvaluateAccuracy}(\mathbf{l}'_i) > f_i$  **then**
- 22:        $\mathbf{l}_i \leftarrow \mathbf{l}'_i$
- 23:     **end if**
- 24:   **end for**
- 25: **end for**
- 26:  $\mathbf{g}^* \leftarrow \arg \max_{\mathbf{l} \in \mathcal{L}} \text{EvaluateAccuracy}(\mathbf{l})$
- 27: // Update reputations
- 28: **for** each client  $i$  **do**
- 29:   **if**  $i \in \mathcal{N}'$  **then**
- 30:      $\xi_i \leftarrow (\cos(\mathbf{g}_i, \mathbf{g}^*) + 1)/2$
- 31:      $\rho'_i \leftarrow \min(\rho_i + 0.05\xi_i, 2.0)$
- 32:   **else**
- 33:      $\rho'_i \leftarrow \max(\rho_i \times 0.7, 0.1)$
- 34:   **end if**
- 35: **end for**
- 36: **return**  $\mathbf{g}^*, \{\rho'_i\}$
